15RATIONALE: Sulfur isotope ratio measurements of bulk sulfide from marine sediments 16have often been used to reconstruct environmental conditions associated with their formation. 17In-situ microscale spot analyses by secondary ion mass spectrometry (SIMS) and laser 18ablation multiple-collector inductively coupled plasma mass spectrometry (LA-MC-ICP-MS) 19have been utilized for the same purpose. However, these techniques are not often suitable for 20small (\leq 10 µm) grains or for detecting intra-grain variability.

21**METHODS**: Here, we present a method for the physical extraction (using lithium 22polytungstate heavy liquid), and subsequent sulfur isotope analysis (using SIMS; CAMECA 23IMS 7f-GEO) of microcrystalline iron sulfides. SIMS sulfur isotope ratio measurements were 24made via Cs⁺ bombardment of raster squares with sides of 20-130 μm, using an electron 25multiplier (EM) detector to collect counts of ³²S⁻ and ³⁴S⁻ for each pixel (128x128 pixel grids) 26for between 20 and 960 cycles.

27**RESULTS**: The extraction procedure did not discernibly alter pyrite grain-size distributions. 28Apparent inter-grain variability in 34 S/ 32 S in 1-4 µm-sized pyrite and marcasite fragments 29from isotopically homogeneous hydrothermal crystals was ~ ±2‰ (1 σ), comparable to the 30standard error of the mean for individual measurements (\leq ±2‰, 1 σ). In contrast, grain-31specific 34 S/ 32 S in modern and ancient sedimentary pyrites and marcasites can have inter- and 32intra-grain variability >60‰. Distributions of intra-sample isotopic variability are consistent 33with bulk 34 S/ 32 S values.

34**CONCLUSIONS**: SIMS analyses of isolated iron sulfide grains yielded distributions that are 35isotopically representative of bulk ³⁴S/³²S values. Populations of iron sulfide grains from 36sedimentary samples record the evolution of the S-isotopic composition of pore water sulfide 37in their S-isotopic compositions. These data allow past local environmental conditions to be 38inferred.

39Iron sulfide minerals, particularly pyrite (FeS₂), represent a substantial geologic reservoir of 40sulfur. Pyrite is a key constituent of many iron sulfide ore deposits,¹ a common accessory 41phase in an array of igneous and metamorphic rocks,^{2,3} and a nearly ubiquitous mineral in 42marine sedimentary rocks of all ages.⁴ Sedimentary pyrites have diverse morphologies, 43crystal sizes, and S-isotope compositions, and these characteristics have proven to be 44invaluable archives for reconstructing local environmental conditions as well as global-scale 45changes in biogeochemistry.⁵⁻⁸ The S-isotopic composition of pyrite is expressed here in the 46standard delta notation (in units of per mil, ‰) relative to the Vienna Canyon Diablo Troilite 47(VCDT) reference standard for sulfur,⁹

$$\delta^{34} S_{sample} = \left(\frac{R_{sample}}{R_{VCDT}} - 1 \right)$$
 (1)

49where R represents $^{34}S/^{32}S$ ratios.

- Pyrite δ^{34} S values are commonly obtained by bulk extraction of chromium-reducible 51sulfur (CRS), using Cr²⁺ to reduce and volatilize FeS₂ to H₂S gas, which can subsequently be 52trapped as zinc or silver sulfide. Isotope ratios for the isolated CRS can be measured by 53combustion elemental analysis isotope ratio mass spectrometry (EA-IR-MS), 12-17 or by 54solution multiple-collector inductively coupled plasma mass spectrometry (MC-ICP-MS). 55Such approaches yield an integrated δ^{34} S value for the CRS pool and are thus blind to patterns 56of isotopic variability within the pyrite pool. In addition, the CRS pool can potentially also 57include marcasite (FeS₂), elemental S, organic polysulfides, and other metal sulfides in 58addition to multiple morphologies or generations of pyrite. S, 10,111
- 59 The degree of isotopic variability within the pyrite pool is hypothesized to reflect 60depositional conditions and may record critical information about the location(s) and 61condition(s) of pyrite formation.^{8,22} For example, if pyrite in a sample is isotopically 62homogeneous, this would suggest that all grains formed from the same fluid. In contrast, a 63bimodal pyrite δ^{34} S distribution might indicate two distinct sulfide sources, e.g., from 64successive exposure to distinct sulfide-bearing fluids. Pyrites from a single source may also 65have a range of $\delta^{34}S$ values, representing their continuous formation in the presence of an 66evolving sulfide reservoir.^{23,24} In diffusively limited environments like marine sediments, pore 67water sulfate can be drawn down by microbial sulfate reduction (MSR). Sulfate reducers have 68a strong preference for the lighter isotopes of S in sulfate, ^{25,26} which leads to increasingly ³⁴S-69enriched sulfate and sulfide with depth in the sediment.²⁷ As a result, later-formed pyrite 70crystals or the outer layers of large pyrite crystals may be more ³⁴S-enriched than pyrite that 71formed earlier.²³ These distinct scenarios (unimodal distribution, bimodal distribution, or 72evolved source) would not be distinguishable using bulk δ^{34} S values. Therefore, there is great 73potential for a grain-specific method for pyrite S-isotope measurements to enhance our 74understanding of pyrite δ^{34} S records, providing a new dimension of information to inform our 75interpretations of this powerful archive.

Progress has been made using spot analyses by SIMS, $^{1,23,28-38}$ or LA-MC-ICP-77MS, 20,39,40 to make spatially resolved δ^{34} S measurements. Some have already attributed

78detectable intra-sample pyrite $\delta^{34}S$ variability to temporal changes in the S-isotopic 79composition of the fluids from which the pyrites precipitated. The method described here, 80scanning ion imaging by SIMS, is designed to address several of the limitations of currently 81available methods for micro-scale analysis of $\delta^{34}S$ in sedimentary pyrite. First, by rastering 82over grains, scanning ion imaging can generate a continuous record of isotope variations, ²⁹ 83one that can be interrogated at variable spatial resolution after data collection. Previously, 84most SIMS studies of pyrites relied on analyses of fairly large ($\geq 10~\mu m$ -diameter) spots 85within grains. This precludes analyses of many sedimentary pyrites (i.e., those with 86diameters <10 μm). Moreover, while spot analyses can be sufficient to determine the 87presence of inter-grain isotopic variability on larger grains, they are not able to discern intra-88grain variability, ^{31–37} except for the case of unusually large (diameters > ~100 μm) pyrites. ²³

- Additionally, by reducing the primary beam current, we achieve the spatial resolution 90necessary to measure inter- and intra-grain $\delta^{34}S$ variability in microcrystalline pyrites. In 91comparison, spot analyses are not ideal for many micro-sized pyrites or necessarily even for 92larger pyrites that are composed of many small parts (e.g., framboids). Relatively high 93primary beam currents (e.g., ≥ 1 nA) inherently limit the three-dimensional resolution of 94isotopic measurements. As scanning ion imaging requires the use of very low primary 95beam currents (e.g., ≤ 20 pA) to prevent the saturation of the electron multiplier detector, 96the associated low sputter rates and small diameter of the focused primary beam (≤ 1 µm) 97result in excellent three-dimensional resolution.
- Finally, we introduce a physical extraction procedure to enable pyrite to be 99concentrated for optimized SIMS analyses for samples where pyrite is a trace phase. As 100pyrite is not a high abundance phase in most sedimentary rocks, and grains are often broadly 101disseminated, this limits the number of grains likely to be present at the polished surface of 102a 1-inch round thin section. Additionally, when grains are close to the edge of the sample 103holder, this adversely affects precision. Therefore, the physical extraction of pyrites from 104sedimentary samples is in many cases a necessary precondition for efficient SIMS analysis on 105a sufficient number of grains to characterize the population. Most early physical extraction 106procedures for pyrite used magnetic separation, although because pyrite is only paramagnetic, 107these approaches are inefficient. Alternative separation procedures utilize heavy liquids, Hobbas these represent an opportunity to separate dense phases like pyrite (5.01 g/cm³) from less 109dense, but common insoluble minerals like quartz (2.65 g/cm³) and clays (2-2.7 g/cm³). For 110this study, lithium polytungstate (LST; working density of 2.85 g/cm³) is preferred due to its 111low toxicity and high recyclability.
- In the following, we present the details of our SIMS scanning ion imaging-based 113sulfur isotope analysis procedure. We first test the validity of the method on micron-scale 114fragments of cm-scale isotopically homogeneous hydrothermal pyrite and marcasite crystals. 115By comparing SIMS results to bulk ³⁴S/³²S ratio data obtained via EA-IR-MS, we quantify 116overall analytical biases associated with the method and determine its general limitations in 117order to provide a robust platform for future grain-specific SIMS analyses of modern and 118ancient microcrystalline iron sulfides. By generating continuous ³⁴S⁻ and ³²S⁻ ion maps for

119inter/intra-grain variability and probing variation in hydrothermal crystals, we increase our 120confidence that the observed variation in sedimentary samples is environmentally meaningful 121and not an analytical artefact. Lastly, we apply the method to a set of extensively studied 122sediment samples that are thought to represent distinct styles and histories of pyritization, 123demonstrating its applicability and value to investigations of modern and ancient marine 124sediments.

125Materials & Methods

126Samples

127For use in density separation procedure tests, and as a S-isotopic standard for SIMS 128experiments, we obtained a single large (~2cm-diameter) euhedral pyrite crystal from Ward's 129Science (Rochester, NY), sourced from the San Jose de Huanzala Mine, Peru. The pyrite at 130this locality is of hydrothermal origin, and has been shown in previous studies to be 131stoichiometric FeS₂.⁴⁹ For use as an additional S-isotopic standard for SIMS experiments, we 132obtained a single large (~1cm-diameter) euhedral marcasite crystal from Ward's Science, 133sourced from the Jiří open-pit lignite mine in the Czech Republic. For use in further SIMS S-134isotope experiments, we selected a modern sediment sample from Santa Barbara Basin,⁵⁰ and 135two mid-Cretaceous, Cenomanian-Turonian Ocean Anoxia Event (OAE 2) shale samples 136from the Cismon section in Italy,⁵¹ and the Demerara Rise.⁵²

137Extraction of microcrystalline pyrite from geologic samples

138A \sim 0.5g fragment of the hydrothermal pyrite crystal was ground to a fine powder by mortar 139and pestle, and homogenized. The resulting grain size distribution of the powdered crystal 140('pre'; Table S1) was characterized using a combination of optical microscopy and image 141processing in ImageJ. This involved suspending \sim 0.001 g of powder in ethanol and 142dispersing the sample on a glass microscope slide, then capturing 20 focused images of 143unique parts of the slide through a 40× optical objective. These images were overlain by 14420×20 μ m grids, and a random number generator was used to select 5 grid squares to analyze 145per image. In ImageJ, images of grid squares were scale-calibrated, converted to grayscale, 146and a bandpass filter (filtering large structures down to 10 pixels) and threshold were applied 147to highlight grains. Overlapping/touching grains, or grains with a circularity of <0.9 were 148removed, to approximate the near-sphericity of natural pyrite grains. Grain areas were 149calculated for the remaining particles using the 'Analyze Particles' function in ImageJ, and 150grain sizes were estimated by assuming that each grain was perfectly circular in cross-section.

A separation procedure was then carried out on subsamples of the powdered crystal. 152Three 0.01 g aliquots of powder were added to 45 mL of LST in three 50 mL centrifuge 153tubes. These tubes were mixed for a minute using a vortex mixer at the highest speed, then 154placed in an ultrasonic bath (35 kHz) for 15 minutes. Tubes were then spun in a centrifuge for 15538 minutes at 3000 rpm, as these conditions were estimated (see equation 2) to allow \geq 0.5 μ m 156diameter spherical pyrite fragments to settle in LST. Particle settling time (t_s) was estimated 157using Stokes' Law^{54,55}:

$$t_{s} = \frac{9 \,\mu h}{2(\rho_{p} - \rho_{l}) R_{p}^{2} a} \tag{2}$$

159where μ is the dynamic viscosity of the fluid (0.011 Pa·s for LST), h is the height of the liquid 160in the centrifuge tube (10 cm in our setup), ρ_p and ρ_l are the mass densities of the particles and 161the fluid (5.01 and 2.85 g/cm³ for pyrite and LST), R_p^2 is the radius of the settling particle 162squared, and a is the centrifugal acceleration (in m/s²), given by:

$$a = \omega^2 r \tag{3}$$

164where r is the centrifuge radius (18 cm in our setup), and ω is angular velocity (in radians/s), 165given by:

$$\omega = 2\pi f \tag{4}$$

167where f is the rotational frequency (50/s in our setup). It should be noted that the settling time 168calculated using equation 2 is likely an underestimate due to hindering effects such as 169particle-particle and particle-container interactions. After centrifugation, settled fragments 170were removed from the tubes using a plastic micro-pipette, placed in new 50 mL centrifuge 171tubes, rinsed and spun down (5 minutes at 2000 rpm) five times in deionized water. This 172process was repeated three times sequentially (Table S1, 'a-c') for each 0.01 g portion of 173powder. In order to more closely approximate insoluble residues from marine sediments, the 174extraction procedure was also repeated for a 1:99 mixture of pyrite and ~300 μ m-sized quartz 175grains (0.01 g pyrite, 0.99 g quartz), and a 1:99 mixture of pyrite and ~50 μ m-sized quartz 176grains. Each extract was dried and weighed, and grain size distributions were calculated for 177the first sequential extracts for the pure pyrite ('post'), pyrite with large quartz grains 178('postQz'), and pyrite with small quartz grains ('postSmQz').

A shatter box was employed to powder the Cretaceous-age shale samples, for no 180longer than one minute. There was no obvious sign of sulfide mineral fragmentation after this 181procedure. For the Santa Barbara Basin sediment sample, one gram of dried sediment was 182powdered gently in a mortar and pestle. For the Cretaceous shales and modern Santa Barbara 183Basin sediment, carbonate minerals were removed by three sequential 10-minute treatments 184with 6M hydrochloric acid, before the insoluble residue was rinsed five times with deionized 185water and dried in an oven at 60°C for 24 hours. The insoluble residues were then powdered 186by mortar and pestle prior to performing a single density separation as described above on 1870.25 g aliquots of each.

188Mounting of samples

189Dried iron sulfide samples were carefully transferred onto the surface of the base of a 1-inch 190round acrylic mould that had been coated with a release agent, isooctane. After adding iron 191sulfide samples and powdered hydrothermal pyrite and marcasite for use as internal S-192isotopic standards (kept separate using a Parafilm M grid), the upper half of the mould was

193then attached and filled with epoxy (2:1:13.63 ratio mixture of 1-(2-aminoethyl) piperazine; 1941,-8-diamino-p-menthane; and Araldite 506 epoxy resin). After degassing in a vacuum oven 195for 10 minutes, and removing any remaining bubbles with a 21G needle, the epoxy was cured 196for 72 h at 60° C in an oven. The epoxy was then removed from the mould and sequentially 197polished with a 6 µm polishing pad, 3 µm diamond paste, and 1 µm diamond paste, in order 198to expose the standards and sample, and minimize surface topography and roughness. After 199using Raman microprobe analysis (1 mW laser power and 50x objective)⁵⁶ and optical 200microscopy (50x objective, plane-polarized light) to confirm the presence and mineralogy of 201analyte at the surface of the polished epoxy pucks, the pucks were coated with ~50 nm thick 202Au to ensure conductivity for SIMS analysis.

203**Sample imaging**

204For iron sulfide extracts from the Cismon and Demerara shale samples, \sim 20 µg aliquots were 205mounted on carbon tape, coated with 5 nm Au by physical vapor deposition using a Kurt J. 206Lesker PVD 75 (Jefferson Hills, PA, USA), before representative mineral textures were 207imaged by Scanning Electron Microscopy (SEM) using a JEOL JSM-7100 LVF Field 208Emission SEM (Tokyo, Japan).

209Bulk sulfur isotope analyses

210To determine $\delta^{34}S$ values for the hydrothermal pyrite and marcasite crystals, and to assess 211their degrees of isotopic homogeneity, three fragments of each crystal were randomly 212selected, and powdered in an agate mortar. Small (~125 µg) aliquots of powdered FeS₂ were 213loaded into tin capsules with 1-2 mg V₂O₅, combusted in a Costech ECS 4010 Elemental 214Analyzer (Valencia, CA, USA); $^{34}S/^{32}S$ ratios were then measured in a Thermo Scientific 215Delta V Plus isotope ratio mass spectrometer (Waltham, MA, USA), and corrected to VCDT 216by bracketing analyses of in-house VCDT-calibrated ZnS, BaS and BaSO₄ standards. For the 217fragments of pyrite and marcasite, the average $\delta^{34}S$ values measured by EA-IR-MS were –1.0 218± 0.1‰ (1 σ , n=3) and 4.6 ± 0.2‰ (1 σ , n=3), respectively. The same analytical procedure was 219used to generate 'bulk' $\delta^{34}S$ data for the pyrite physically extracted from the Cismon section 220sample.

221SIMS sulfur isotope analyses

222After pre-sputtering by Cs⁺ bombardment for 300 seconds with a 1 nA beam current at the 223desired raster size, sulfur isotopic ratio experiments were performed in "scanning ion imaging 224mode" by Cs⁺ bombardment (beam diameter of <1 μ m, current of ~10 pA) of raster squares 225of 20-130 μ m, using an electron multiplier (EM) detector on a CAMECA IMS 7f-GEO 226(Fitchburg, WI, USA) at Washington University in St. Louis to collect counts of ³²S⁻ and ³⁴S⁻ 227for each pixel (grids of 128x128 or 256x256 pixels) for between 20 and 960 planes (1 minute 228per plane).

The size of each exposed grain analyzed was measured using calibrated optical 230microscope images before analyses. The SIMS stage was x-y calibrated to a stitched optical 231microscope image of the epoxy puck using digital video camera footage of the gold-coated 232sample surface in the analysis chamber. Raw isotope ratios for each grain were calculated by 233taking the mean $^{34}S^{-}/^{32}S^{-}$ ion count ratio of a central area of the grain over the multiple

234analysis planes. Various corrections were applied to data, including a dead-time correction, an 235interpolation of $^{34}S^{-}$ counts to align in time with those on $^{32}S^{-}$, and a quasi-simultaneous 236arrival (QSA) effect correction. The magnitude of the QSA undercounting correction is 237proportional to instrument transmission, i.e., the number of secondary ions reaching the 238detector per incident primary ion. However, it is not possible to determine primary currents 239<50 pA very accurately on the 7f-GEO instrument. Therefore, the ratio of the QSA coefficient 240(β) to the primary ion flux (J) was used to facilitate the correction. 57 β/J values were 241determined for each session, via data obtained from the internal standard grains, using the 242relationship:

$$R_{\rm exp} = R_{cor} + (\beta/J) \times {}^{34}S_{\rm exp} \tag{5}$$

244where $R_{\rm exp}$ and $^{34}S_{\rm exp}$ are dead time corrected $^{34}S/^{32}S$ ratio and ^{34}S count rate, respectively, and 245 $R_{\rm cor}$ is the QSA corrected $^{34}S/^{32}S$ ratio. The instrumental mass fractionation was then corrected 246for by calculating the mineral-specific fractionation factor ($^{34}\alpha$) based on the mean raw (from 247SIMS) and expected (from EA-IR-MS) $\delta^{34}S$ value of the population of internal hydrothermal 248pyrite or marcasite fragments and dividing the average $^{34}S^{-/32}S^{-}$ ratio of each environmental 249iron sulfide grain by the appropriate $^{34}\alpha$.

250Results

251Extraction procedure

252The grain size distribution of the powdered hydrothermal pyrite crystal ('pre') suggested that 25392.5% of grains were >0.5 μm, the smallest size expected to settle in our setup, so this was 254set as the expected maximum level of recovery. Recovery of initial pyrite (summarized in 255Table S1) was highest for 'post' (58±12%, 1σ) and for 'postSmQz' (57%), but lower for 256'postQz' (23±4%, 1σ). Initial extractions ('a') recovered most pyrite, and subsequent 257extractions ('b' and 'c') were generally not effective in recovering the remaining pyrite. At 258grain sizes larger than 1.1 μm (close to the lower limit of what can be precisely measured on 259the 7f-GEO; Figure 1), grain size distributions of pre, post, postSmQz and postQz ('1a') were 260all similar, within the power of our technique to resolve differences (Figure 1, inset). 261Therefore, the extraction procedure does not impose a grain-size bias for grains \geq 1.1 μm.

262[insert Figure 1]

Recovery of pyrite for the Santa Barbara Basin sediment sample was estimated to be 26441.3% by comparing extract mass to previously measured total S abundance. Extract purity 265for the Cismon section FeS₂ was estimated using EA to be 61% and by comparing extract 266mass to CRS abundance, FeS₂ recovery was estimated to be 54.5%, which again closely 267matches measured recovery for our synthetic sediment samples. In addition, the physically 268extracted iron sulfides had a bulk δ^{34} S value of $-42.5 \pm 0.2\%$, whereas the bulk untreated 269sample had a δ^{34} S value of $-42.1 \pm 0.2\%$. The agreement between the isotopic compositions 270of the chemically and physically extracted iron sulfides indicates that the physical extraction 271procedure did not impart any isotopic bias on the population of iron sulfides in the sample.

272SIMS sulfur isotope experiments

273Hydrothermal pyrite

274Sub-angular, randomly oriented 1-3 μm diameter fragments of the hydrothermal pyrite 275(Figure 2A) were analyzed in a 50 um raster over 375 cycles (30 seconds integration time per 276ion, per cycle; Figure 2B; see Jones et al⁵⁸ for justification). The fragment-to-fragment 277reproducibility (n=14, 1σ) was ±1.9‰ (Figure 1C; Figure S1A), and using the EA-IRMS 278bulk δ^{34} S value of $-1.0 \pm 0.2\%$, $^{34}\alpha_{pyrite}$ was calculated to be 0.9964 (Table S2). The standard 279error associated with individual fragments was ±0.9 to ±3.3‰ (1σ; Figure 2C), with an 280average of ±2.1‰ (Figure S1A), and was better for larger fragments due to better counting 281statistics (Figure S2). Lateral intra-fragment reproducibility in the largest fragment (Figure 282S3A) was ±2.8‰ (n=8, 1σ; Figure S3B, C), with an average standard error of ±3.0‰ (1σ; 283Figure S3C).

284[insert Figure 2]

285Hydrothermal marcasite

286Sub-angular, randomly oriented 1-5 μ m diameter fragments of the hydrothermal marcasite 287crystal (Figure 3A) were analyzed in a 50 um raster over 375 cycles (30 seconds integration 288time per ion, per cycle; Figure 3B). The fragment-to-fragment reproducibility (n=25, 1 σ) was 289±2.3% (Figure 3C; Figure S1B), and using the EA-IRMS bulk δ^{34} S value of +4.6 ± 0.2%, 290 $^{34}\alpha_{marcasite}$ was calculated to be 1.0014 (Table S2). The standard error associated with 291individual fragments was between ±1.1 to ±5.2% (1 σ ; Figure 3C), with an average of ±2.6% 292(Figure S1B), and was better for larger fragments due to improved counting statistics (Figure 293S2). Lateral intra-fragment variability in the largest fragment (Figure S4A) was ±1.9% (n=6, 2941 σ ; Figure S4B, C), with an average standard error of ±3.6% (1 σ ; Figure S4C).

295[insert Figure 3]

296Modern sedimentary pyrites (Santa Barbara Basin)

297Optical microscope images (Figure 4A) suggest that the majority of pyrites in this modern 298sediment sample are 1-80 μm-diameter irregular aggregates of intergrown euhedral-to-299anhedral microcrystals. A minority of pyrites are framboidal (i.e., 5-10 µm-diameter pseudo-300spheroidal aggregates of equant, equidimensional, non-intergrown microcrystals), while some 301grains display a mixture of the framboidal and irregular textures (Figure 4A). The one 302pristine framboid measured by SIMS (Grain 27; Figure 4B-C) had a δ^{34} S_{pyrite} value of $-42.7 \pm$ 3031.5% (1 σ ; Figure 4C), the irregular aggregates (Figure 4B) had an average δ^{34} S_{pyrite} value of $304+24.2 \pm 2.9\%$ (1 σ , n=47; Figure 4C), and five grains displaying mixed textures (Grains 1–2, 30517, 19, and 22; Figure 4B) had δ^{34} S_{pyrite} values between +0.1 ± 0.8% (1 σ) and +16.4 ± 0.7% 306(1σ; Figure 4C; Table S2). Within the mixed textured grains, the framboidal areas were 307usually depleted in ³⁴S with respect to the irregular areas (Figure S5). Within the solely 308irregular aggregates, variability in δ^{34} S was minimal (±3.5‰, 1 σ , n=11; Area 14 in Figure 4; 309Figure S6) and comparable to the average standard error associated with measurements 310($\pm 2.6\%$, 1 σ ; Figure S6D). Where present, the apparent variability had no consistent 311directionality (Figure S6). The average standard error associated with individual fragments 312was $\pm 1.5\%$ (1 σ ; Figures 4C, D). The sample average $\delta^{34}S_{pyrite}$ value was $\pm 21.7 \pm 10.3\%$ (1 σ ;

313n=53; Figure 4D). The $\delta^{34}S_{pyrite}$ variability in this sample (Figures 4C, D) overlaps the bulk $314\delta^{34}S_{CRS}$ value for the sample of +16.1‰, ⁵⁰ and is not normally distributed (Figure 4D).

315[insert Figure 4]

316Ancient sedimentary pyrites and marcasites (Cismon and Demerara Rise) 317Optical microscope images of mounted extract from Cismon (Figure S7) display the presence 318of both euhedral marcasite and framboidal pyrite, as supported by laser Raman microprobe 319spot analyses and SEM (Figure S8). Pyrite and marcasite grains from Cismon measured by 320SIMS had average δ^{34} S values of $-41.9 \pm 5.2\%$ (1σ ; n=113) and $-48.5 \pm 5.1\%$ (1σ ; n=161; 321Figure 5), and cemented pyrite aggregates had an average δ^{34} S value of $-42.2 \pm 0.6\%$ (1σ ; 322n=2), as compared with the bulk δ^{34} S composition of -42.1%. There was little intra-grain 323 δ^{34} S variation in marcasite grains (average $1\sigma = \pm 2.9\%$, compared to an average intra-grain 324standard error of $\pm 3.5\%$, 1σ ; Figure S9A-D), and very little intra-grain δ^{34} S variation in pyrite 325grains (average $1\sigma = \pm 3.7\%$, compared to an average intra-grain standard error of $\pm 2.9\%$, 1σ ; 326Figure S9E-H).

327[insert Figure 5]

As with the Cismon section sample, optical microscope images of mounted extract 329 from Demerara (Figure S10) display the presence of both euhedral marcasite (in this case 330 mostly in irregular aggregates) and framboidal pyrite, as supported by laser Raman 331 microprobe spot analyses and SEM (Figure S8). Pyrite and marcasite grains measured by 332 SIMS had average δ^{34} S values of $-24.9 \pm 11.2\%$ (1σ ; n=45) and $-26.1 \pm 6.1\%$ (1σ ; n=19; 333 Figure 6), as compared with a bulk δ^{34} S composition of $-24.4 \pm 0.2\%$. In contrast to those 334 from the Cismon section sample, pyrites from the Demerara sample sometimes featured 335 larger, more easily-resolved intra-grain variation in δ^{34} S (average $1\sigma = \pm 6.0\%$, compared to 336 an average intra-grain standard error of $\pm 1.6\%$, 1σ ; Figures 6, S11A-D). This was even more 337 obviously the case for the marcasites (average $1\sigma = \pm 13.3\%$, compared to an average intra-338 grain standard error of $\pm 2.1\%$, 1σ ; Figures 6, S11E-H). Generally, the largest relative 339 enrichments in 34 S were found near the edges of pyrite framboids (Figure S11A-B), and in the 340 extremities of irregular aggregates of both minerals (Figure S11C-H).

341[insert Figure 6]

342Discussion

343Evaluating the method

344Despite incomplete recovery (reasons for which are discussed in the Supplement), the 345similarity between artificial pyrite grain size distributions before and after being treated with 346the extraction procedure (Figure 1) suggests that this protocol does not bias pyrite grain size 347distributions, even when grains are at the lower end of sizes that can be measured using a 7f-348GEO SIMS instrument (\sim 1 μ m) or when they are mixed with large proportions of quartz 349grains. This is important because where grain size variability exists in populations of iron 350sulfide grains in sedimentary samples, such variability may be coupled to isotopic

351variability;²⁸ thus, a size bias in extraction protocol could produce an isotopic bias in the 352measured results relative to the parent sample.

Analysis of fragments of hydrothermal pyrite and marcasite crystals, used as S-354isotopic standards for our other SIMS experiments, resulted in little inter- (Figures S1-2) or 355intra-fragment (Figures S3-4) variability in δ^{34} S (i.e., the standard deviation of measurements 356between or within fragments was always smaller than the average standard error associated 357with those inter- or intra-grain measurements). Therefore, the method is suitable for the 358detection of the potentially large variations in δ^{34} S that may exist within or between 359sedimentary iron sulfide grains. 23,24,28,29,37

The average SIMS δ^{34} S values for iron sulfides from samples from the Cismon section $361(-45.8 \pm 6.1\%, 1\sigma; n=274;$ Figure 5) and the Demerara Rise ($-25.3 \pm 11.2\%, 1\sigma; n=45;$ 362Figure 6) are close to the previously reported bulk δ^{34} S_{CRS} values (-42.1%, and -24.4%, 363respectively). $\delta^{51,52}$ The Santa Barbara Basin pyrites' average δ^{34} S value ($+21.7 \pm 10.3\%, 1\sigma; 364$ n=53; Figure 4) is 5.6% higher than the bulk δ^{34} S_{CRS} value (+16.1%, 0.00) but the large range of 365grain-specific values (-42.7% to +28.9%) overlaps with the bulk value, and corresponds to a 366textural dichotomy between isotopically light framboids and isotopically heavy irregular 367aggregates. Accordingly, the discrepancy between bulk and average grain-specific δ^{34} S values 368is likely the result of insufficiently representative sampling of the two textural components 369for SIMS analysis. The extraction and analytical procedures introduced in this study are not 370likely to give rise to any isotopic biases, though areas analysed by SIMS may not always be 371entirely representative of the bulk iron sulfides in a sample. In the future, this could be 372rectified by ensuring that SIMS analyses of each texture are in proportion to their relative 373abundances.

Importantly, the method documents $\delta^{34}S$ variability within a sample, which is critical 375for interpreting bulk 'CRS' $\delta^{34}S$ values. Inter-grain (Figures 4-7), intra-grain (Figures S5-6, 376S9, S11), and inter-mineralogy (Figures 5-6) variability all contribute to a single bulk $\delta^{34}S$ 377value from CRS extraction (which integrates both pyrite and marcasite, as well as potentially 378other reduced S phases). Each type of variability should be considered and investigated when 379making environmental interpretations based on $\delta^{34}S$ data.

380[insert Figure 7]

381Interpreting sedimentary δ^{34} S data

382The three samples studied here are distinct in terms of their bulk δ^{34} S values and internal δ^{34} S 383variability (Figure 7). Thus, they can be used to map out the environmental phase space that 384can be explored using this SIMS ion imaging method. The first step to this process is to 385consider that iron sulfide minerals formed in marine sediments record the δ^{34} S composition of 386reduced sulfur-bearing aqueous phases (e.g., hydrogen sulfide or polysulfides) in the fluid 387from which they nucleate or grow. In most cases, this fluid is likely to be pore water in 388marine sediments, but pyrites can also precipitate from sulfide-rich water columns. Segments 389Secondly, iron sulfide mineral growth requires a source of iron. Different sources (i.e., 390mineral or aqueous) are differentially reactive to aqueous reduced sulfur species,

391therefore the extent to which iron sulfide minerals record spatio-temporal changes in the $\delta^{34}S$ 392composition of aqueous sulfur is highly dependent on the abundance, mineralogy, and 393speciation of available iron.⁸

The sample from Santa Barbara Basin comprises silt-clay sized material from one of 394 395the "gray layers" that have been hypothesized to represent extremely rapid deposition 396associated with major flood events. ^{61–63} Rapid deposition results in pore water sulfate being 397consumed faster than it is supplied. ²² We predict a broad range of pyrite δ^{34} S values 398corresponding to progressive pyrite precipitation in such a scenario. Berelson et al⁵⁰ found 399that iron disulfides from the sample are highly ³⁴S-enriched in bulk, and are predominantly 400irregular aggregates of pyrite. In this study, we found that the irregular aggregates noted by 401Berelson et al⁵⁰ are even more highly-enriched in ³⁴S than the bulk sample (Figure 4), and 402 feature very little intra-grain δ^{34} S variability (Figure S6). Conversely, framboidal pyrites are 403depleted in ³⁴S, and feature irregular overgrowths that are usually relatively enriched in ³⁴S 404(Figure S5). This clearly implies a spatial or temporal separation in the growth of these two 405textures. The ³⁴S-depleted framboids likely formed in a relatively open, sulfate-replete 406system, such as pore waters close to the sediment-water interface, or in the water column 407(e.g., in sinking particles harboring anoxic microenvironments⁶⁴). In contrast, the ³⁴S-enriched 408irregular aggregates likely formed in a system in which rapid MSR led to ³⁴S-enriched 409aqueous sulfate and sulfide. 22,65 MSR must have greatly outpaced pyrite formation, leading to 410the build up of an aqueous reduced sulfur pool in pore fluids with a similar S-isotopic 411composition to the initial sulfate reservoir. The majority of pyrite in the sample precipitated 412 from this agueous reduced sulfur pool. The high rate of MSR relative to the rate of pyrite 413formation was very likely a result of the slow kinetics of iron reduction.⁶⁰

Sediments from the Cismon section are thought to represent nearly the opposite end-415member case to Santa Barbara Basin, with very low bulk CRS δ^{34} S values (avg. -42.7%). 51,52 416These values have been interpreted to represent pyrite formation in a system that was open to 417the diffusive supply of sulfate, 66,67 so a narrow intra-sample range of δ^{34} S values is expected. 418Accordingly, we find that the sample lacks both inter-grain (Figures 5, 7) and intra-grain 419(Figure S9) δ^{34} S variability. Individual pyrite grain δ^{34} S values ($-41.9 \pm 5.2\%$, 1σ ; n=113) 420and marcasite grain δ^{34} S values ($-48.5 \pm 5.1\%$, 1σ ; n=161; Figure 5) cluster close to the bulk 421CRS δ^{34} S value, suggesting that the S-isotopic composition of aqueous reduced sulfur species 422in the fluid from which the iron sulfides formed was not highly variable. This is consistent 423with a scenario in which all iron sulfides (pyrite framboids, pyrite cements and marcasite 424euhedra) formed either in the water column or in sediments where the rate of sulfate diffusion 425from the water column exceeded the rate of sulfate consumption by MSR.

Finally, sediments from the Demerara Rise are thought to represent an intermediate 427case between the Cismon section and Santa Barbara Basin, with a corresponding bulk CRS 428 δ^{34} S value of -24.4% for our sample. This black shale sample (422.8 m depth, ODP Leg 207, 429Hole 1258a) was deposited under a euxinic water column, so sulfate consumption by MSR 430very likely outpaced the diffusive replenishment of sulfate. ⁵² Therefore, a larger intra-sample 431range of δ^{34} S values relative to the Cismon section sample is expected. Accordingly, the

432sample from Demerara Rise features a large amount of $\delta^{34}S$ variability – both inter- (Figures 4336, 7) and intra-grain (Figure S11), in pyrites and marcasites. The mean $\delta^{34}S$ values of 434marcasite and pyrite grains (Figure 6) are very similar. However, unlike in the Cismon 435section sample, both pyrite framboids (Figure S11A), and pyrite (Figure S11C) and marcasite 436clusters (Figure S11E, G), have large internal ranges in $\delta^{34}S$, of ~10‰ to 65‰, with more ³⁴S-437enriched material on the outer layer of framboids or in discrete zones in the extremities of 438clusters. This pattern is evidence for the formation of these grains over a time interval with 439evolving pore fluid $\delta^{34}S$. As in the case of the Santa Barbara Basin sample, these results 440suggest that MSR led to ³⁴S-enrichment of aqueous sulfate and sulfide with time in the 441sediment. We also see a 'tail' of relatively ³⁴S-enriched pyrites in the $\delta^{34}S$ distribution 442(Figure 7), which suggests that there must have been sufficiently abundant and reactive iron 443available to sustain iron sulfide mineral growth as pore waters became progressively ³⁴S-444enriched. So

Marcasite is thought to be a relatively rare mineral in sedimentary rocks, most notably 445 446occurring in black shales. ^{68,69} The environmental implications of its presence are still poorly 447understood. Experimental work suggests that a very low pH is required for its formation. ⁷⁰ 448Given that pyrite oxidation can give rise to acidic conditions, ⁷¹ this has led to the suggestion 449that the partial oxidation of pre-existing pyrite led to the formation of marcasite in black 450shales. ^{68,69} However, given that black shales are thought to represent low pO_2 conditions in 451water column, it is unclear how early diagenetic pyrite oxidation could have occurred in these 452sediments. In addition, the general isotopic similarity between the highly abundant marcasite 453in the Demerara and Cismon samples used in this study, and the coexisting pyrite (Figures 5-4546), suggests that the two minerals share a formation history. Therefore, marcasite formation 455was probably not a result of low pH conditions created by pyrite oxidation. Another way to 456generate more acidic pore waters than are typical for marine sediments is oxic organic matter 457respiration. ⁷¹ This process could have been exacerbated by the high organic loading at both 458sites.⁵² Future work using SIMS will provide further constraints on the relative abundance of 459marcasite and the genetic relationship(s) between pyrite and marcasite in black shales.

In conclusion, the methods detailed here provide a basis for the physical extraction 461and accurate and precise sulfur isotopic measurement of microcrystalline iron sulfide grains 462within a range of sediments and sedimentary strata. The minimal size-biasing during the 463extraction procedure suggests that the iron sulfide extracts obtained should be isotopically 464representative of the bulk sample, as confirmed by our samples. The low apparent inter-grain 465variability between isotopically identical pyrite (and marcasite) micro-fragments implies that 466the sulfur isotope composition of diverse environmental populations of ≥ 1 µm-sized pyrites 467and marcasites can be measured accurately and precisely by SIMS ion imaging. Micrometer-468scale intra-grain variability in δ^{34} S can also be measured. Ultimately, it is possible to use this 469approach to unpack local environmental (geochemical and depositional), metabolic, and 470diagenetic signals recorded in iron sulfide grains in both unlithified sediments and rocks. 471With this in mind, the method could be applied to the both the modern and ancient bulk 472sedimentary records of δ^{34} S to test previous wide-ranging interpretations of apparent 473excursions in bulk data. 72-74
